Perfect Epidemics

17 January 2025

1: Introduction to Perfect Simulation

- Propp & Wilson (1996) invented exact simulation / Coupling from the Past (CFTP) / perfect simulation;
- The term "perfect simulation" (WSK, 1998) should make you suspicious: perfection is never achieved. This is why the term was chosen!
- Key ideas of "classic CFTP":
 - extend simulation *backwards* through time not forwards;
 - exploit monotonicity (couple maximal and minimal processes);
 - seek coalescence.
- Simplest possible example: random-walk-CFTP (can boost to use Ising model to do simple image reconstruction).

Perfect Epidemics

2025-01-16

1: Introduction to Perfect Simulation

Here's a very brief summary of CFTP / perfect simulation.

- 1. Jim Propp described the discovery of CFTP as like walking down the street and suddenly noticing a 50\$ bill lying on the ground.
- 2. In particular, "exact simulation" cannot somehow miraculously defeat numerical approximation error :-).
- 3. We will cover these key ideas in a single very specific example.
- 4. Propp & Wilson (1996) show how to vary random walk CFTP to get exact samples for a critical Ising model (Persi Diaconis: "Like seeing the landscape of Mars for the first time"). The Ising model with an external field can be used to model images, hence CFTP can be used for image reconstruction.

Perfect Epidemics

17 January 2025

Classic CFTP for a simple random walk (I)

- Consider a simple random walk on $\{0, 1, 2, 3, 4, 5, 6, 7, 8, 9\}$.
 - $\mathbb{P}\left[+1 \text{ jump }\right] = p \in (0,1), \text{ while } \mathbb{P}\left[-1 \text{ jump }\right] = 1-p, \text{ except that }$
 - ightharpoonup at state 9 replace +1 jump by staying still, and
 - \triangleright at state 0 replace -1 jump by staying still.
- Conventional MCMC picks a starting point, then runs the simple random walk for long time till approximate equilibrium.
- How long? One way to *estimate* this is to run two (or several?) coupled copies till they meet. If probability of meeting by time T is high, then deviation of X_T from equilibrium is statistically small;
- Generally not true that location at coupling is a draw from equilibrium.

W S Kendall, S B Connor (Warwick, York)

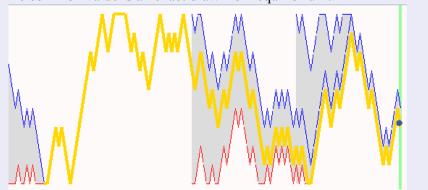

Perfect Epidemic

17 January 2025

4/36

Classic CFTP for a simple random walk (I)

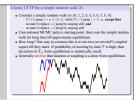

- So now start at top (9) and bottom (0) at negative time -T, run to time 0.
- ullet If not coupled by time 0, than back-off to time -2T and repeat.
- May need to iterate back-off doubling several times.
- When coupled, top and bottom yield a common value at time 0.
- The common value is an exact draw from equilibrium!

Warwick Statistics

Perfect Epidemics

2025-01-16

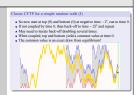

This random process is asymmetric simple random walk on the integers, but forbidding any transitions outside the specified state-space.

- 1. The process is irreducible _and_ aperiodic, so equilibrium is a truncated Geometric distribution (hint: use reversibility to check this!).
- 2. Conventional MCMC is overkill here, of course: we could simulate directly from the equilibrium distribution.
- 3. This observation was originally formalized by Aldous. Here we use 'synchronous coupling variants are possible but not particularly useful.
- 4. Clearly not true in our case: coupling can only occur at 0 or 9!
- 5. In this case the blue and red evolutions can only couple at a boundary, so self-evidently the value at time of coupling cannot be a draw from the equilibrium!

Perfect Epidemics

- 1. Ideally one needs to choose T neither too small nor too large. But the result is not particularly sensitive to this.
- 2. Very important that one doesn't introduce different jumps for the same time -t in this binary back-off! We must re-use randomness.
- 3. The binary back-off procedure means, if T is initially set to be too small then the extra work that is required is only ever a factor of 4!
- 4. Re-use of randomness means there is now no point in continuing: the common value at time 0 will be the same however far we extend into the past with further back-offs.
- 5. Why is the common value an exact draw from equilibrium? Informally, because one would get the same result however far one backed-off: therefore the draw is effectively a draw from time −∞. The golden thread can be viewed as a perfect draw from the last segment of such a simulation (this sort of device is very well-known to ergodic theorists). Remarkably, this can easily be converted into a fully rigorous proof!

2: A short section on some theory about CFTP

- What about cases where monotonicity fails? or there isn't a sensible "maximal" process? Ideas (WSK, 1998):
 - cross-couple upper and lower envelope processes;
 - ▶ dominate by amenable "dominating process" (time-reversible, can draw from equilibrium, can couple target processes below dominating process).
- Theoretical limits: in principle we can show that
 - ► Classical CFTP equivalent to uniform ergodicity (Foss & Tweedie, 1998);
 - ▶ *Dominated CFTP* achievable under geometric ergodicity (WSK, 2004);
 - ▶ Dominated CFTP can work in some **non**-geometrically ergodicity cases (Connor & WSK, 2007a; *nb* corrigendum Connor & WSK, 2007b).
- *Dominated CFTP* can be used to carry out perfect simulation for stable point processes (WSK & Møller, 2000);
- Detailed expositions: WSK (2005), Huber (2015). (Want to implement CFTP in R? see WSK, 2015.)

3: Perfect Epidemics: a challenge problem for CFTP

Many important inferential questions (Cori & Kucharski, 2024).

Simplest models (versus UK model with 10⁶ agents!, Fraser & Others, 2023):

S-I-R deterministic epidemic: susceptibles s, infectives i, removals r (constant total population s + i + r = n):

$$\begin{array}{rcl} s' & = & -\alpha \, s \, i \,, \\ i' & = & (\alpha \, s - \beta \,) \, i \,, \\ r' & = & \beta \, i \,. \end{array}$$

S-I-R stochastic epidemic: a Markov chain (S, I, R) with transitions

Infection:
$$S \to S-1$$
, $I \to I+1$ at rate αSI , Removal: $I \to I-1$, $R \to R+1$ at rate βI .

Perfect Epidemics

Both models make an unrealistic assumption: homogeneous mixing.

(Locally finite) point processes cannot in general be treated using Classic CFTP, because the "top" pattern would have points *everywhere*. More generally, the "in principle" results encourage us to try CFTP out on a wide variety of models (For example, for M/G/k multiserver queues, Connor & WSK, 2015; Connor, 2020).

- 1. To be computationally effective, the WSK (1998) fixes still require some associated notion of partial order and (perhaps weak) amenability of the dominating process.
- 2. Basic ideas: use the notion of regenerative sets ("small sets"), and (Foster-)Lyapunov arguments. Note that the recipes given for these tend not to be computationally practical: they simply show the possibility of (possibly computationally infeasible) CFTP. They are intended as a challenge: when can one find *practical* methods?
- 3. This is the end of the visual introduction to CFTP. People who are interested in CFTP from a practical point of view may find it useful to work through WSK (2015).

Perfect Epidemics

___3: Perfect Epidemics: a challenge problem for CFTP

Here are two classical models (one deterministic, one stochastic) from mathematical epidemiology. Even the exceedingly simple case of deterministic S-I-R permits only *partial* closed-form solution.

The assumption of homogeneous mixing of population greatly simplifies the mathematics *and* statistics. Without this assumption one ends up with huge numbers of parameters, which is very bad news statistically speaking. A lot of research has been done on how to deal with more realistic models! (For example, the UK model using 1000000 agents mentioned here!)

However in this work we deal only with perfect simulation for homogeneous mixing. Before running, one must learn to walk!

The first question asked about a new epidemic

"What is the R-number?"

The R-number is $\alpha s_0/\beta$: mean number of new infectives produced per infective at *start* of epidemic with initially s_0 susceptibles.

Whittle (1955)'s threshold theorem: R-number $\gg 1$ means positive chance of epidemic infecting significant proportion of the population.

Wikipedia: "The British-registered *Diamond Princess* was the first cruise ship to have a major [COVID-19] outbreak on board, with the ship quarantined at Yokohama from 4 February 2020 for about a month. Of 3711 passengers and crew, around 700 people became infected and 9 people died."

4: Inference on the R-number

Important, because the R-number controls severity of epidemic. However:

- Modelling is tough. *Either* massive assumptions (homogeneous mixing) *or* very many parameters;
- Inference is really tough: hard to get information about infection times;
- It is all especially tough in early stages. Answers are most needed when hardly any information is available (a simplified example for a Warwick UG second-year statistics module shows how tough this can be);
- Markov chain Monte Carlo (MCMC) can be used (see next slide) but what about burn-in?
- Can we use perfect simulation?

Perfect Epidemics

The "R-number" was the subject of continuing interest throughout the COVID-19 pandemic!

Notice that the "R-number" is as much a social construct as a biological one, and in real situations will interact in subtle and complicated ways with behaviour.

We will seek to make headway in using perfect simulation to aid inference.

5: An easier question

W S Kendall, S B Connor (Warwick, York)

An absurdly simple variant of contact tracing:

"When did the infections occur, supposing we only observe removals?" (Gibson & Renshaw, 1998; O'Neill & Roberts, 1999; Gibson & Renshaw, 2001)

- Thus n, α , β are known, removal times are observed, but unobserved infection times must be inferred.
- ② Visualize n timelines, along which incidents are scattered:
 - potential removals, activated if timeline is infected;
 - ▶ potential infections, activated if timeline is infected *and* if designated target timeline is lowest uninfected timeline.
- **1** Poisson point processes of appropriate rates yield an S-I-R epidemic.
- First step: evolve whole S-I-R trajectory in *algorithmic time* (alter potential infections and removals using immigration-death in discrete algorithmic time).
- **1** Result: *trajectory-valued chain*, unconditioned S-I-R as equilibrium.

- 1. Instead of trying to tackle inference concerning the parameters, let's concentrate on the large number of nuisance parameters provide by (typically unobserved) infection times.
- 2. This is a compromise: instead of tracking individuals as in the stochastic epidemic model, we effectively track the numbers of individuals in various categories.
- 3. Poisson point processes generate incidents, which then collectively influence the S-I-R trajectory.
- 4. I learned the phrase "algorithmic time" from Andrew Stuart.

 We move from Poisson points spread out along timelines to discrete immigration-death processes producing patterns that evolve in algorithmic time.
- 5. But we shall quickly move to *continuous* algorithmic time.

Perfect Epidemics

2025-01-16

Colour-coding distinguishes infections from deaths. Note that infections need to specify which timeline is going to be infected.

- For an infection incident to be activated, it must sit on an infected portion of its timeline and must point to the least of the uninfected timelines (calculating at the process time of the incident).
- For a removal incident to be activated, it must sit on an infected portion of its timeline.

in infected region, then remove lowest infected (purple disk if different timeline).

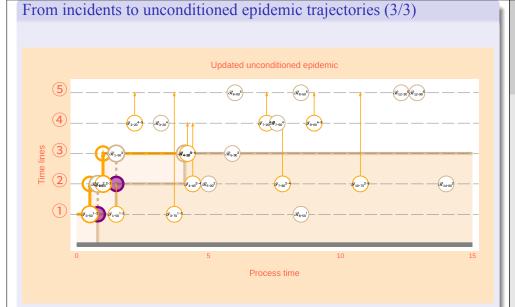

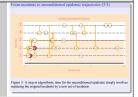

Figure 3: A step in algorithmic time for the unconditioned epidemic simply involves replacing the original incidents by a new set of incidents.

Perfect Epidemics

2025-01-16

12/36

An update in algorithmic time, if there is no conditioning, simply involves replacement of one set of incidents by another.

17 January 2025

Crucial technical point

- Updates in algorithmic time τ are then (algorithmic-)time-reversible: so restriction to subset S of state-space (of activated removals occurring precisely at specified set of times) implies a new equilibrium which is the old equilibrium conditioned to lie in S.
- For later purposes it is convenient to stage the replacement as follows:
 - \bullet Replace removals (Rs);

 - 3 Replace infections (Is).
- Re-express using continuously varying τ . Process time runs over [0, T].
 - For $2nT < \tau < (2n+1)T$, update old Rs with times in $(0, \tau 2nT)$;
 - ② For $\tau = (2n+1)T$, resample timelines (not times) of Rs;
 - **⑤** For $(2n+1)T < \tau < (2n+2)T$, update old Is in $((2n+2)T \tau, T)$.
- Thus the original update is expressible as a (continuous) composition of updates, each of which satisfies detailed balance in equilibrium.
- The connection "restriction=conditioning" is thereby preserved.
- Crucially, step 2 ensures composition action is irreducible over S! (So equilibrium under conditioning is unique.)

 Crucially, step 2 ensures composition action is irreducible

In the case of discrete algorithmic time, it seems that arranging for conditioning would involve horrendous computation. Instead we "unroll' into continuous algorithmic time.

Intuitively, we analyze first removals and then infections "pixel-by-pixel" along the process time axis.

It turns out to be convenient to work forwards in time for removals, then backwards in time for infections – and to re-assign random timelines (but not times) for removals in between these two phases.

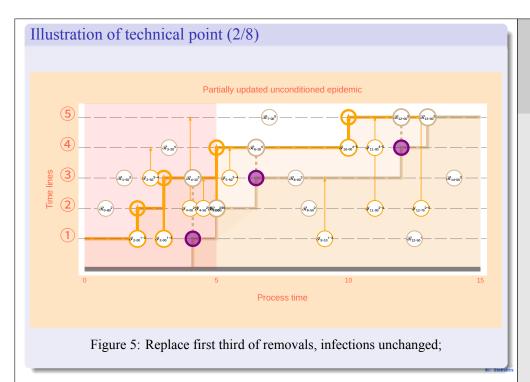

W S Kendall, S B Connor (Warwick, York) Perfect Epidemics 17 January 2025 14/36 Illustration of technical point (1/8)

Perfect Epidemics

Figure 4. No change yet to removable or inflictions,

Here is the initial configuration again.

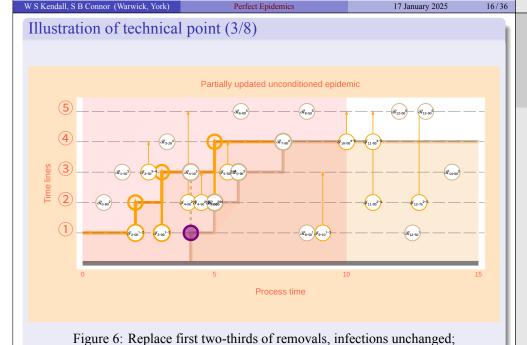

2025-01-16

Now we use the immigration-death process of removals to work forwards along the process-time axis removing old removals and adding new ones. At present we are not applying conditioning. Here we are 1/3 of the way through dealing with removals.

Perfect Epidemics

2025-01-16

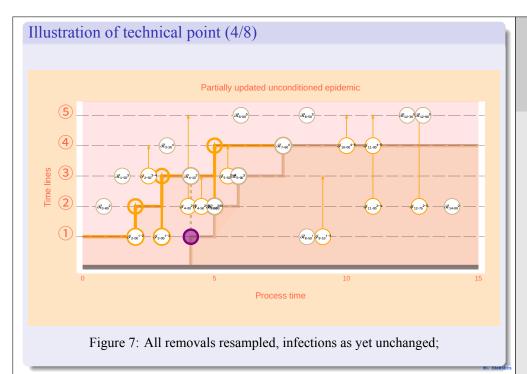

17 January 2025

17 January 2025

17/36

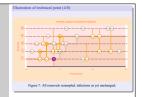

Here we are 2/3 of the way through dealing with removals. Flip backwards and then forwards one slide, and confirm that the light-orange nodes with vertical arrows (infections) are not changed at this stage.

2025-01-16

All removals have now been processed. Because we are not yet conditioning, all old removals have now been removed, and all new removals have been added.

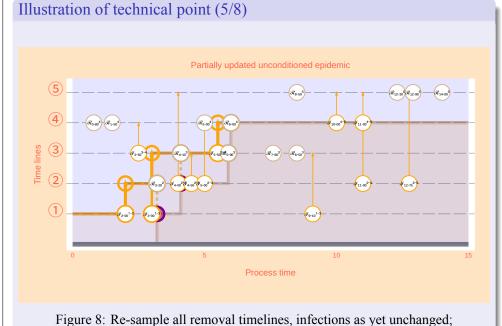

Notice that nothing was done for this simulation in the last 1/3 of removal work, not surprising since most timelines were by then removed, and so there isn't much scope for removals to arrive.

W S Kendall, S B Connor (Warwick, York)

Perfect Epidemics

17 January 2025

19/36

W S Kendall, S B Connor (Warwick, York)

Perfect Epidemics

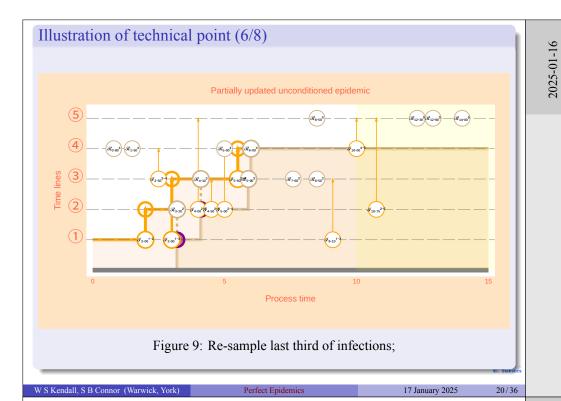

2025-01-16

At this stage we now re-sample the timelines for all removals. Since we are not conditioning, this results in a big change.

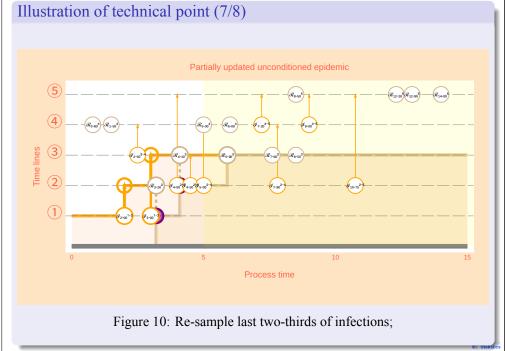

No nodes change time, but timelines for removal nodes are all re-sampled.

- 1. When we proceed to consider conditioning on observing certain removals, the observed ("conditioned") removals will not have been moved so far (their removal will have been rejected!) but at this stage the change in timeline will be accepted if the dynamics do not then lead to a change in conditioned removals.
- 2. On the other hand, timeline-resampling for an inactivated removal will be rejected if it leads to that removal being activated, but statistically the effect will be the same as if it wasn't re-sampled.

Now we resample infections, but this time working backwards through process time. Here is how matters stand after 1/3 of the work is done. Again, there is little scope for anything to be done yet: one infection has been dropped.

Perfect Epidemics

W S Kendall, S B Connor (Warwick, York)

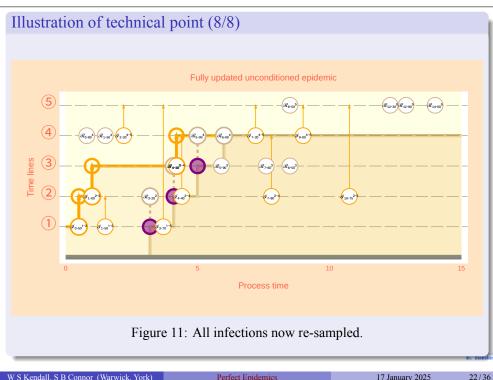

Perfect Epidemics

2025-01-16

21/36

17 January 2025

And here is how matters stand after 2/3 of the work is done. Much more change at this stage.

Perfect Epidemics

2025-01-16

Finally the entire process time range is dealt with. In this unconditioned case all removals and infections are removed and replaced by new ones. Under conditioning, however, each individual decision (to remove, resample, or introduce) has to be tested to see if it affects the pattern of conditioned removals. We now need to consider how to do this efficiently, but also in a manner that allows us to reason about the crucial monotonicity.

W S Kendall, S B Connor (Warwick, York)

17 January 2025

Perfect Epidemics

2025-01-16

Conditioning on observed removals

Monotonicity is a key concept here. (Note however that we can still sometimes generate perfect simulation algorithms even when monotonicity does not obtain: we don't need to do this here but should bear it in mind for more general problems in the future.)

- 1. We can also deal with "unbounded" sample space using the notion of Dominated CFTP.
- 2. The heart of the matter lies in establishing (some variant of) monotonicity.
- 3. Additionally, for a complicated algorithm such as this one, it is important to test the underlying logic by implementing the algorithm in computer code (which has a way of revealing false hidden assumptions!).

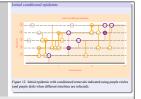

Conditioning on observed removals

- The trajectory-valued chain is *dynamically reversible*, in *continuous* algorithmic time.
- Irreducibility is *vital* (otherwise equilibrium depends on starting point). Consequently:
 - conditioned removals must be able to change timeline (but not time of occurrence);
- Forbidding removal of observed removals, and forbidding creation of new activated removals, yields a modified chain whose invariant probability measure conditions on observed pattern of removals. Implications:
 - a removal can be introduced only if it doesn't activate;
 - ▶ a conditioned removal timeline can be altered only if it doesn't de-activate:
 - ▶ an infection cannot be removed if that action loses a conditioned removal;
 - ▶ an infection can be introduced only if no new observed removals result.
- Does this produce a *feasible* and suitably monotonic algorithm?
- Housekeeping details required to establish that monotonicity still works. Key notions: last feasible epidemic (LFE) and no-fly zone (NFZ).

Figure 12: Initial epidemic with conditioned removals indicated using purple circles (and purple disks when different timelines are infected).

Perfect Epidemics

2025-01-16

Here is a slightly different initial epidemic, which includes *conditional removals*, indicated by purple circles.

- Essentially we change it in the same way as in the unconditioned case (working "pixel-by-pixel"), but forbidding any change if that breaks conditioning.
- Dealing with removals is easy: it amounts to removing all inactivated removals and replacing them with a new bunch, and then resampling the conditional removal timelines, accepting only those changes which do not de-activate the conditional removals.
- But we need to take more care about whether or not we can take away or add in *infections*.

W S Kendall, S B Connor (Warwick, York)

Perfect Epidemics

17 January 2025

24/36

Conditional epidemic update

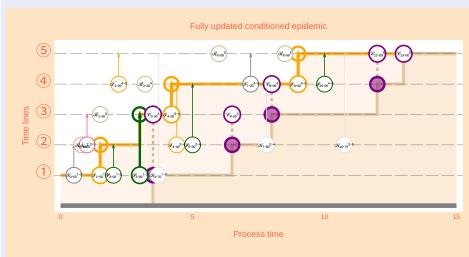

Figure 13: Epidemic updated under restriction: all conditioned removals remain activated, no new removals are activated. Green infections have been "perpetuated".

Perfect Epidemics

2025-01-16

Here is the result of the update, which we now explain general terms. We have noted removals are easy. Re-sampling the conditioned removal timelines is a simple accept-reject step for each conditioned removal.

The key to dealing with infections that target the infected region is also rather simple:

- 1. Always add them (because it won't make a difference).
- 2. Delete them only if it is clear that this will not result in a conditioned removal falling out of the infected region.
- 3. Implementation amounts to referring to a recursively-defined *last feasible epidemic* (LFE). The LFE coincides with the actual epidemic trajectory exactly when deletion of the infection in question will lead to a conditioned removal falling out of the infected region; therefore this deletion is rejected and the retained infection is designated as **perpetuated** (coloured green!). Otherwise the infection can be deleted.
- 4. Infections targetting the susceptible region are trickier, and we will discuss them briefly below.

Figure 14: LFE computed recursively working right-to-left: the slowest sequence of infections deals with all infected timelines in order (includes perpetuated infections).

No-fly zone (NFZ)

Fully updated conditioned epidemic with NFZ

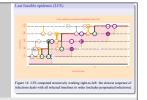

Fully updated conditioned epidemic with NFZ

The state of the state

Figure 15: NFZ computed recursively working right-to-left: it traces the region of timelines that must not be infected if one is not to activate unobserved removals.

Perfect Epidemics

2025-01-16

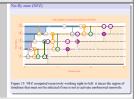

First we draw the LFE. Because it is defined recursively working backwards in process time, it can be computed in entirety from the updated conditional epidemic.

- Of course, when computing the update, we have to compute it set-by-step when working backwards in process time.
- Here there are three discrepancies between LFE and epidemic trajectory, over intervals [1.5,2.0],4.2,5.0, and [9.0,10.0].
- At times 2.00, 3.00, 5.00 and 10.00 there are perpetuations (an old infection has to be retained to ensure conditioning is not broken); at the second time 3.00 the perpetuation ends up forming part of the epidemic trajectory.

A relatively simple induction argument shows that the LFE depends monotonically on the epidemic trajectory!

Perfect Epidemics

2025-01-16

The NFZ is used to decide whether to accept proposals of infections targeting the susceptible region. More complicated than LFE; two phenomena interact.

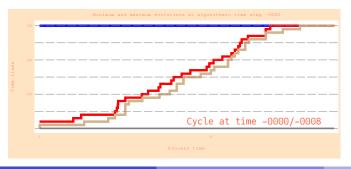

- 1. An infection rooted in the infection zone must be assessed to see whether its introduction would lead to activating a removal, because it connects the infectious zone to a timeline which would lead to such an activation (a "no-fly" portion of the timeline);
- 2. An infection rooted in the susceptible zone may be such that it makes a portion of its timeline *before* its time into "no-fly".

Infection proposals at 0.5 and 7.2 are rejected as they would infect the NFZ, activating a removal. An infection proposal at 1,0 extends the NFZ.

The NFZ is evaluated recursively, working backwards in process time. A more involved induction argument shows that the NFZ depends monotonically on the epidemic trajectory. This implies monotonicity of the algorithmic-time evolution of the conditioned epidemic: hence CFTP is feasible!

Example

- Smallpox outbreak in a closed community of 120 individuals in Abakaliki, Nigeria (much studied! see page 125 of Bailey, 1975).
- Assume
 - first observed removal is also the first removal: under a plausible improper prior we can then deduce what is the distribution of infectives I_0 at time 0;
 - ▶ *all* removals are recorded;
 - ▶ no further removals after last observed removal (makes life easier).
- Coding in *julia* (Bezanson *et al.*, 2017), we can construct a perfect simulation GIF yielding a draw from unobserved pattern of infections.

2025-01-16

W S Kendall, S B Connor (Warwick, York)

17 January 2025

28/36

So what?

- Why this emphasis on unobserved infections given fixed α and β , when we need inference on R-number α n/β for unknown α and β ?
- Good question. But a re-weighting argument allows us to get (unbiased) estimates based on different α and β . The perfect simulation provides exact simulation-based computation to integrate out pattern of unobserved infections.
- So (next steps after Connor & WSK, 2024)
 - estimate likelihood test statistic for specified α and β ;
 - construct steepest ascent algorithm (in effect, variant of Robbins-Monro stochastic optimization) to find maximum a posterior estimates of α and β ;
 - or even, with some computational effort, compute the entire posterior joint density for α and β !
- Finally: generalize to other suitable compartment models?

Perfect Epidemics

2025-01-16

Example.

We could vary the assumption concerning the initial and final numbers of infectives while still using essentially the same perfect simulation algorithm! This amounts to presuming some Bayesian prior knowledge.

- How do we allow for the (unobserved) number of initial infectives being unobserved?
- Use an independence sampler: draw from the (unconditioned) number of initial infectives, accept if this leads to observed removals exactly at the list of conditioned removals.
- (One can alternatively employ a random-walk Metropolis sampler, so long as the prior for the initial number of infectives is suitably monotonic.)

Technical note:

The simulation implementation uses *julia* (Bezanson *et al.*, 2017), which combines rapid development, an expressive syntax (very useful for involved algorithms), and remarkably fast execution using very good "just in time" compi-

Perfect Epidemics └─So what?

In effect, perfect simulation supplies a well-behaved stochastic integration mechanism, reducing an MCMC algorithm to use a technique equivalent to a much more amenable Monte Carlo calculation. Other compartment models presenting varying degrees of challenge:

- 1. Split population into a small number of interacting sub-populations;
- 2. (For purposes of insight even if impractical.) Treat each individual as a sub-population on its own;
- 3. Allow parameters to change at specific times of day or week;
- 4. Allow for some activated removals to be unobserved!

Conclusion

- If MCMC burn-in is a concern, try to build a perfect simulation!
- CFTP works even for significantly complex and relevant models of real-life phenomena.
- Of course detailed models resist perfect simulation (but it will be helpful to compare with a simpler model using fewer parameters).
- Still to be done: statistical estimation of parameters, generalization to other compartment models.
- Thank you for your attention! **QUESTIONS?**

A "near-maximal" configuration

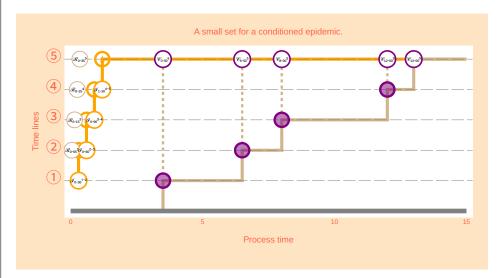

Figure 16: A conditional epidemic in which all activated infections occur before time 3.0, also before smallest observed removal time.

Perfect Epidemics 2025-01-16

A "near-maximal" configuration

- 1. For a "near-maximal configuration", we set relevant infections to occur in order on or before a fixed small time $\delta = 1.5 > 0$, where 2δ is smaller than any of the conditioned removal times.
- 2. All inactivated removals have to occur before their respective infections (in order to avoid activation).
- 3. Variants on this construction can be used to show that CFTP for the perfect epidemic must coalese in finite time;
- 4. However to get a sensible stochastic bound on coalescence time would require a lot more work!
